The Effect of Chronic Renal Failure on Thyroid Hormones

Layla K. Ali

*Nursing Department, Koya Technical Institute

Abstract

Chronic renal failure (CRF) affects thyroid function in multiple ways, including low circulating thyroid hormone concentration, altered peripheral hormone metabolism, disturbed binding to carrier proteins, possible reduction in tissue thyroid hormone content, and increased iodine store in thyroid glands. The target of study is to find a relationship between chronic renal failure and thyroid function. In addition, we tried to study the effect of CRF on serum creatinine dependent on the level of thyroid hormones (T3 and T4) and thyroid stimulating hormones (TSH). Forty patients with chronic renal failure (20 male, 20 female) were enrolled in this study in addition to forty healthy individual as control group (20 male, 20 female). The age ranged from (25-65) years. T3, T4, TSH, urea, uric acid and creatinine were measured in each of the two groups. The results revealed statistically significant reduction in T3 and T4 while there is elevation in TSH, urea, uric acid and creatinine in the patients group compared to the control group.

Key word: Chronic Renal Failure, Thyroid Hormones.

Introduction

The thyroid gland produces two major related hormones thyroxine and triiodothyronine, commonly called T4 and T3, respectively, which play essential roles in the complete lack in the processes of metabolism, growth and development in most vertebrate tissue. Complete lack of thyroid secretion usually causes the basal metabolic rate to fall 40 to 50 percent below normal and extreme excesses of thyroid secretion can increase the basal metabolic rate to 60 to 100 percent above normal [1, 2]. Thyroid secretion is controlled primarily by thyroid stimulating hormone (TSH) secreted by the anterior pituitary gland. Small amount of reverse triiodothyronine (rT3) and other compounds are also found in venous blood [1]. The synthesis of the thyroid hormones requires (150 -200 μg) of iodine daily. Most dietary iodide is reduced to iodine before absorption. Iodine after conversion to iodide in stomach is rapidly absorbed from the gastrointestinal tract and distributed in the extra cellular fluid [3]. There are three thyroid hormones binding proteins in human plasma: albumin, with high capacity and low affinity; thyroxine binding globulin (TBG), with low capacity and high affinity, and transthyretin (TTR) with an intermediate capacity [4]. Thyroid hormone levels are under strict control; this is achieved mainly by feed-back inhibition through: Hypothalamic-pituitary – thyroid axis (HPTA); thyrotrpin – releasing hormone (TRH).l. Thyroid hormone regulation, thyroid stimulating hormone (TSH) secretion or negative – feed back system on pituitary secretion of (TSH); and factors altering (TSH) secretion, such as somatostatin dopamine and/or glucocorticoids [5]. Some changes in thyroid function test results are observed in most of the acute and chronic illnesses (i.e. renal diseases, cardiovascular diseases, inflammatory conditions and pulmonary diseases). Alteration in thyroid function test findings may reflect changes in production of thyroid hormone by effects on the thyroid itself, on the hypothalamic - pituitary thyroid axis, on peripheral tissue metabolism of the hormones, or a combination of these effects [6].

A general conviction exists that patients with thyroid function test abnormalities do not have hypothyroidism despite the low serum hormone levels in blood and low T₄ in most of the tissues. Many patients with non-thyroid illness (NTI) also receive drugs that affect thyroid hormone regulation and metabolism. This discussion does not consider pharmacological interference an intrinsic part of the spectrum of changes in hypothalamic–pituitary thyroid function that occur in (NTI). Assessment of thyroid function in patients with non-thyroid illness is difficult. Many of them have low serum concentrations of both T₄ and T₃ and their serum (TSH) concentration may also have been low. Previously, these patients were thought to be euthyroid, and the term euthyroid – sick syndrome was used to describe the laboratory abnormalities. It is possible that the changes in thyroid function during severe illness are protective in that they prevent excessive tissue catabolism. There are two important general principles in laboratory assessment of thyroid: thyroid function should not be assessed in seriously ill patients unless there is strong suspicion of thyroid dysfunction. When Thyroid dysfunction is suspected uncritically ill patients, measurement of serum (TSH) alone is inadequate for the evaluation of thyroid function. Chronic kidney disease is defined as either kidney damage or a decreased kidney glomerular filtration rate (GFR) of less than 60 ml / min / 1.73 m² for 3 or more months. The causes of the chronic kidney disease could be due to primary and secondary glomerular disease, tubulointerstitial disease and vascular disease. Previous studies on thyroid function tests indicate lower thyroid hormone concentration (T₃, T₄) with normal TSH in haemodialysed patients compared with normal subjects. Thyroid gland produces T₄ but only 20% of the most metabolically active thyroid hormone T₃ and 5% to 8% as the calorigenically inactive reverse T₃ (rT₃) hormone and T₄ in tissues such as liver, kidneys and muscles. Haemodialysis employs the process of diffusion across a semi permeable membrane to remove toxic products and excess fluid from the blood, while adding desirable components. This aim of this work is to evaluate thyroid gland function in chronic renal failure patients as an attempt to find a relationship between chronic renal failure and thyroid dysfunction.

**Materials and Methods**

**-Selection of Subjects & Blood Collection**

Forty patients with chronic renal failure (20 male, 20 female) were enrolled in this study in addition to forty healthy individual as control group (20 male, 20 female). The age ranged from (25–65) years. To compare the significance of the difference in the mean values in comparison groups, student t - test was applied; P ≤ 0.05 was considered statistically significant. Patients with ischemic heart disease, diabetes mellitus and thyroid disease (such as hypothyroidism, hyperthyroidism and goiter) were excluded. Five ml of venous blood were aspirated from control group and CRF patients at 8:00 - 9:00 am. Blood samples were collected into plain test tubes and centrifuged after 30 minutes of collection for 10 minutes at 3000 rpm. Serum was frozen at -20°C till used in determination of T₃, T₄, TSH, ura, uric acid and creatinine.

**- Determination of T3, T4 and TSH**

Total triiodothyronine (T₃), total thyroxin (T₄) and thyroid stimulating hormone (TSH) were evaluated using VIDAS (T₃) REF 30403, VIDAS (T₄) REF 304041 and VIDAS (TSH) REF 30400 from biomerix (France) respectively. The principle of the quantitative determination of T₃, T₄ and TSH combines an enzyme immunoassay competition method with a final fluorescence detection (EIFA).

**- Determination of Urea**

Urea concentration levels were determined in serum by using enables end point enzymatic (Urease – modified Berthelot reaction) in which urease hydrolyzes urea in an alkaline medium. The ammonium ions react with the salicylate and hypochlorite to form a green colored indophenol. The reaction is catalyzed by the sodium nitroprusside.

**- Determination of Uric Acid**

Uric acid concentrations were determined by using uricase- peroxidase - chromogen sequence in which hydrogen peroxide is formed and reacts as the colors of the reaction.

**- Determination of Creatinine**

Creatinine levels were evaluated according to Jaffes method. The production of orange color after the addition of alkaline picrate. The color is proportional to the concentration of creatinine.
Results and Discussion

Table (1) shows the (mean ± SD) of T3, T4, TSH, urea, uric acid and creatinine concentrations in sera of patients with chronic renal failure and control group, in which P ≤ 0.05 was considered significant.

This study shows highly significant reduction in T3 and T4 concentration in patients serum with CRF compared to control group (P ≤0.05). Intensive studies revealed that renal insufficiency affects thyroid function in multiple ways, including altered peripheral hormone metabolism, disturbed binding to proteins, reduction in tissue thyroid hormone content, and iodine accumulation in thyroid gland [14,15]. Another explanation is that the reason for the decrease in T4 could be attributed to multiple factors such as deficiency of thyroxine binding globin (TBG) [16,17]. In the present study serum TSH was measured in CRF and control groups. CRF group had TSH above normal range. Some authors interpret this TSH elevation as a sign of recovery from a hypothyroid state despite the distortion of TSH in some euthyroid patients with NTI, who have significant elevation of TSH due to underlying primary hypothyroidism [18]. Highly significant elevation was found in urea, uric acid and creatinine in serum of CRF patients compared to control group. Increase in urea in renal failure are caused by impaired ability to excrete proteinaceous catabolites because of marked reduction in glomerular filtration rate (GRF). Increases in serum creatinine are also a result of decreased renal excretion [19].
